Abstract

This document provides a set of "torture tests" for implementers of the Signaling Compression (SigComp) protocol. The torture tests check each of the SigComp Universal Decompressor Virtual Machine instructions in turn, focusing in particular on the boundary and error cases that are not generally encountered when running well-behaved compression algorithms. Tests are also provided for other SigComp entities such as the dispatcher and the state handler.

1. Introduction

This document provides a set of "torture tests" for implementers of the SigComp protocol, RFC 3320 [2]. The idea behind SigComp is to standardize a Universal Decompressor Virtual Machine (UDVM) that can be programmed to understand the output of many well-known compressors including DEFLATE and LZW. The bytecode for the chosen decompressor is uploaded to the UDVM as part of the SigComp message flow.

The SigComp User's Guide [1] gives examples of a number of different algorithms that can be used by the SigComp protocol. However, the bytecode for the corresponding decompressors is relatively well behaved and does not test the boundary and error cases that may potentially be exploited by malicious SigComp messages.

This document is divided into a number of sections, each containing a piece of code designed to test a particular function of one of the SigComp entities (UDVM, dispatcher, and state handler). The specific boundary and error cases tested by the bytecode are also listed, as are the output the code should produce and the number of UDVM cycles that should be used.

Each test runs in the SigComp minimum decompression memory size (that is, 2K), within the minimum number of cycles per bit (that is, 16) and in tests where state is stored 2K state memory size is needed.

2. Torture Tests for UDVM

The following sections each provide code to test one or more UDVM instructions. In the interests of readability, the code is given using the SigComp assembly language: a description of how to convert this assembly code into UDVM bytecode can be found in the SigComp User's Guide [1].

The raw UDVM bytecode for each torture test is given in Appendix A.

Each section also lists the number of UDVM cycles required to execute the code. Note that this figure only takes into account the cost of executing each UDVM instruction (in particular, it ignores the fact that the UDVM can gain extra cycles as a result of inputting more data).

2.1. Bit Manipulation

This section gives assembly code to test the AND, OR, NOT, LSHIFT, and RSHIFT instructions. When the instructions have a multitype operand, the code tests the case where the multitype contains a fixed integer value, and the case where it contains a memory address at which the 2-byte operand value can be found. In addition, the code is designed to test that the following boundary cases have been correctly implemented:

- 1. The instructions overwrite themselves with the result of the bit manipulation operation, in which case execution continues normally.
- 2. The LSHIFT or RSHIFT instructions shift bits beyond the 2-byte boundary, in which case the bits must be discarded.
- 3. The UDVM registers byte_copy_left and byte_copy_right are used to store the results of the bit manipulation operations. Since no byte copying is taking place, these registers should behave in exactly the same manner as ordinary UDVM memory addresses.

                                        pad (2)
                                        pad (2)
at (128)
JUMP (start) ; Jump to address 255
at (255)
:start
; The multitypes are values
; $start = 448 (first 2 bytes of AND instr) AND ($start, 21845) ; 448 \& 21845 = 320 = 0 \times 0140 OR ($a, 42) ; 0 \mid 42 = 42 = 0 \times 002a
OR ($a, 42)
NOT ($b) ; \sim 0 = 65535 = 0 \times \text{ffff}
LSHIFT ($a, 3) ; 42 << 3 = 336 = 0 \times 0150
RSHIFT ($b, 65535) ; 65535 >> 65535 = 0 = 0 \times 0000
OUTPUT (64, 4) ; Output 0x0150 0000
; The multitypes are references
AND (\$a, \$start) ; 336 & 320 = 320 = 0x0140
OR ($a, $a)
                            ; 320 \mid 320 = 320 = 0 \times 0140
                            NOT ($a)
LSHIFT ($b, $a) ; 0 << 65215 = 0 = 0 \times 0000
RSHIFT ($a, $b) ; 65215 >> 0 = 65215 = 0 \times 1000
                            ; 65215 >> 0 = 65215 = 0xfebf
                            ; Output Oxfebf 0000
OUTPUT (64, 4)
END-MESSAGE (0, 0, 0, 0, 0, 0)
```

The output of the code is $0x0150\ 0000$ febf 0000. Executing the code costs a total of 22 UDVM cycles.

2.2. Arithmetic

This section gives assembly code to test the ADD, SUBTRACT, MULTIPLY, DIVIDE, and REMAINDER instructions. The code is designed to test that the following boundary cases have been correctly implemented:

1. The instructions overwrite themselves with the result of the arithmetic operation, resulting in continuation as if the bytes were not bytecode.

2. The result does not lie between 0 and 2^16 - 1 inclusive, in

which case it must be taken modulo 2^16.

```
3. The divisor in the DIVIDE or REMAINDER instructions is 0 (in
     which case decompression failure must occur).

OUTPUT (64, 4)
                           ; output 0x0000 0000
; The multitypes are references
ADD (\$b, \$start) ; 0 + 1 = 1 = 0 \times 0001
                                ; If the message is 0x00
SUBTRACT ($b, $type) ; 1 - 65535 = 2 = 0x0002

MULTIPLY ($b, $b) ; 2 * 2 = 4 = 0x0004

DIVIDE ($a, $b) ; 0 / 4 = 0 = 0x0000
```

REMAINDER (\$b, \$type) ; $4 \% 65535 = 4 = 0 \times 0004$

```
OUTPUT (64, 4) ; output 0x0000 0004 ; If the message is 0x01, $type = 0 ; so decompression failure occurs at ; REMAINDER ($b, $type) ; If the message is 0x02, $type = 1 so ; $b becomes 0 and decompression failure ; occurs at DIVIDE ($a, $b)
```

END-MESSAGE (0, 0, 0, 0, 0, 0)

If the compressed message is 0x00, then the output of the code is $0x0000\ 0000\ 0000\ 0004$ and the execution cost should be 25 UDVM cycles. However, if the compressed message is 0x01 or 0x02, then decompression failure occurs.

2.3. Sorting

This section gives assembly code to test the SORT-ASCENDING and SORT-DESCENDING instructions. The code is designed to test that the following boundary cases have been correctly implemented:

 The sorting instructions sort integers with the same value, in which case the original ordering of the integers must be preserved.

```
at (128)

SORT-DESCENDING (256, 2, 23)

SORT-ASCENDING (256, 2, 23)

OUTPUT (302, 45)
END-MESSAGE (0, 0, 0, 0, 0, 0)

```

The output of the code is 0x466f 7264 2c20 796f 7527 7265 2074 7572 6e69 6e67 2069 6e74 6f20 6120 7065 6e67 7569 6e2e 2053 746f 7020 6974 2e, and the number of cycles required is 371.

2.4. SHA-1

This section gives assembly code to test the SHA-1 instruction. The code performs four tests on the SHA-1 algorithm itself and, in addition, checks the following boundary cases specific to the UDVM:

- 1. The input string for the SHA-1 hash is obtained by byte copying over an area of the UDVM memory.
- 2. The SHA-1 hash overwrites its own input string.

0x4f46 0452 ebb5 6393 4f46 0452 ebb5 6393 4f46 0452

Executing the code costs a total of 17176 UDVM cycles.
```

2.5. LOAD and MULTILOAD

This section gives assembly code to test the LOAD and MULTILOAD instructions. The code is designed to test the following boundary cases:

- 1. The MULTILOAD instruction overwrites itself or any of its operands, in which case decompression failure occurs.
- 2. The memory references of MULTILOAD instruction operands are evaluated step-by-step rather than all at once before starting to copy data.

```
LOAD (128, 132)
                                ; address 128 contains 132 = 0 \times 0084
LOAD (130, $location_a)
                               ; address 130 contains 132 = 0 \times 0084
LOAD ($location_a, 134)
                               ; address 132 contains 134 = 0 \times 0086
LOAD ($location_b, $location_b); address 134 contains 134 = 0x0086
OUTPUT (128, 8)
                                 ; output 0x0084 0084 0086 0086
INPUT-BYTES (1, start_lsb, decompression_failure)
MULTIPLY ($start, 2)
ADD ($start, 60)
MULTILOAD ($start, 3, overlap_start, overlap_end, 128)
:position
set (overlap_start, (position - 7))
MULTILOAD ($start, 4, 42, 128, $location_a, $location_b)
:end
set (overlap_end, (end - 1))
OUTPUT (128, 8)
END-MESSAGE (0, 0, 0, 0, 0, 0)
:decompression_failure
DECOMPRESSION-FAILURE
The INPUT-BYTES, MULTIPLY, and ADD instructions give the following
values for $start = $64 just before the MULTILOADs begin:
          $start before 1st MULTILOAD
Input
0x00
                60
0x01
                62
0x02
                64
Consequently, after the first MULTILOAD the values of $start are the
following:
          $start before 2nd MULTILOAD
Input
0x00
          128
0 \times 01
          overlap_end = 177 = last byte of 2nd MULTILOAD instruction
0 \times 02
          overlap_start = 162 = 7 bytes before 2nd MULTILOAD
          instruction
```

Consequently, execution of the 2nd MULTILOAD (and any remaining code) gives the following:

Input Outcome

0x00 MULTILOAD reads and writes operand by operand. The output is 0x0084 0084 0086 0086 002a 0080 002a 002a, and the cost of executing the code is 36 UDVM cycles.

0x01 The first write of the MULTILOAD instruction would overwrite the last byte of the final MULTILOAD operand, so decompression failure occurs.

 0×02 $\,$ The last write of the MULTILOAD would overwrite the MULTILOAD opcode, so decompression failure occurs.

2.6. COPY

This section gives assembly code to test the COPY instruction. The code is designed to test that the following boundary cases have been correctly implemented:

- 1. The COPY instruction copies data from both outside the circular buffer and inside the circular buffer within the same operation.
- 2. The COPY instruction performs byte-by-byte copying (i.e., some of the later bytes to be copied are themselves written into the UDVM memory by the COPY instruction currently being executed).
- 3. The COPY instruction overwrites itself and continues executing.
- 4. The COPY instruction overwrites the UDVM registers byte_copy_left and byte_copy_right.
- 5. The COPY instruction writes to and reads from the right of the buffer beginning at byte_copy_right.
- 6. The COPY instruction implements byte copying rules when the destination wraps around the buffer.

at (64)

```
at (128)
                      ; Set up buffer between addresses 64 & 128
LOAD (32, 16384)
LOAD (byte_copy_left, 64)
LOAD (byte_copy_right, 128)
COPY (32, 128, 33)
                    ; Copy byte by byte starting to the left of
                       ; the buffer, into the buffer and wrapping
                       ; the buffer (inc overwriting the
                       ; boundaries)
LOAD (64, 16640)
                      ; Change the start of the buffer to be
                       ; beyond bytecode
COPY (64, 85, 65)
                      ; Copy to the left of the buffer,
                       ; overwriting this instruction
OUTPUT (32, 119) ; Output 32 * 0x40 + 86 * 0x41 + 0x55,
                       ; which is 32 * '@' + 86 'A' + 'U'
                       ; Set a new small buffer
LOAD (byte_copy_left, 32)
LOAD (byte_copy_right, 48)
MEMSET (32, 4, 65, 1) ; Set first 4 bytes of the buffer to be
                       ; 'ABCD'
COPY (32, 4, 48)
                      ; Copy from byte_copy_right (i.e., not
                       ; in buffer)
OUTPUT (48, 4)
                      ; Output 0x4142 4344, which is 'ABCD'
COPY (48, 4, 46)
                       ; Copy from two before byte_copy_right to
                       ; wrap around the buffer
OUTPUT (32, 2)
                       ; Output 0x4344, which is 'CD'
END-MESSAGE (0, 0, 0, 0, 0, 0)
```

The output is above, and executing the code costs a total of $365\ \mbox{UDVM}$ cycles.

2.7. COPY-LITERAL and COPY-OFFSET

This section gives assembly code to test the COPY-LITERAL and COPY-OFFSET instructions. The code is designed to test similar boundary cases to the code for the COPY instruction, as well as the following condition specific to COPY-LITERAL and COPY-OFFSET:

```
1. The COPY-LITERAL or COPY-OFFSET instruction overwrites the value of its destination.
```

2. The COPY-OFFSET instruction reads from an offset that wraps around the buffer (i.e., the offset is larger than the distance between byte_copy_left and the destination).

The output of the code is above, and the cost of execution is 216
```

UDVM cycles.

2.8. MEMSET

This section gives assembly code to test the MEMSET instruction. The code is designed to test that the following boundary cases have been correctly implemented:

- 1. The MEMSET instruction overwrites the registers byte_copy_left and byte_copy_right.
- 2. The output values of the MEMSET instruction do not lie between 0 and 255 inclusive (in which case they must be taken modulo 2^8).

```

                                   ; previously, the program ends
                                   ; with DECOMPRESSION-FAILURE.
```

END-MESSAGE (0, 0, 0, 0, 0, 0)

:decompression_failure DECOMPRESSION-FAILURE

If the compressed message is 0x62cb, then the code should successfully terminate with no output, and with a total execution cost of 95 UDVM cycles. For different 2-byte compressed messages, the code should terminate with a decompression failure.

2.10. INPUT-BITS

This section gives assembly code to test the INPUT-BITS instruction. The code is designed to test that the following boundary cases have been correctly implemented:

- 1. The INPUT-BITS instruction changes between any of the four possible bit orderings defined by the input_bit_order register.
- 2. The INPUT-BITS instruction inputs 0 bits.
- 3. The INPUT-BITS instruction requests data that lies beyond the end of the compressed message.

:byte_copy_left
:byte_copy_right
:input_bit_order
                                pad (2)
                                pad (2)
:result
                                 pad (2)
at (128)
:start
INPUT-HUFFMAN (result, end_of_message, 2, $input_bit_order, 0,
$input_bit_order, $input_bit_order, $input_bit_order, 0, 65535, 0)
OUTPUT (result, 2)
ADD ($input bit order, 1)
REMAINDER ($input_bit_order, 7)
ADD ($input_bit_order, 1)
JUMP (start)
:end_of_message
END-MESSAGE (0, 0, 0, 0, 0, 0)
```

An example of a compressed message is 0x932e ac71 66d8 6f, which decompresses to give the output 0x0000 0003 0008 04d7 0002 0003 0399 30fe. Executing the code costs 84 UDVM cycles.

As the code is run, the input_bit_order changes through all possible values to check usage of the H and P bits. The number of bits to input each time is taken from the value of input_bit_order. The sequence is the following:

Input_bit_order (bin)	Total bits input by Huffman	Value
000	0	0
010	2	3
100	4	8
110	12	1239
001		
P-bit changed, throw aw	ay 6 bits	
001	1	2
011	3	3
101	10	921
111	14	12542
010		
P-bit changed, throw aw	ay 4 bits	
010	0 - not enough bits so terminate	

Surtees & West Informational [Page 18]

2.12. INPUT-BYTES

This section gives assembly code to test the INPUT-BYTES instruction. The code is designed to test that the following boundary cases have been correctly implemented:

- 1. The INPUT-BYTES instruction inputs 0 bytes.
- 2. The INPUT-BYTES instruction requests data that lies beyond the end of the compressed message.
- 3. The INPUT-BYTES instruction is used after part of a byte has been input (e.g., by the INPUT-BITS instruction).

```
at (64)
:byte_copy_left
                                pad (2)
:byte_copy_rest
:byte_copy_right

                                pad (2)
                                pad (2)
:result
                                pad (2)
                                pad (4)
:output_start
:output_end
at (128)
LOAD (byte_copy_left, output_start)
LOAD (byte_copy_right, output_end)
:start
INPUT-BITS ($input_bit_order, result, end_of_message)
OUTPUT (result, 2)
ADD ($input_bit_order, 2)
REMAINDER ($input_bit_order, 7)
INPUT-BYTES ($input_bit_order, output_start, end_of_message)
OUTPUT (output_start, $input_bit_order)
ADD ($input_bit_order, 1)
JUMP (start)
:end_of_message
END-MESSAGE (0, 0, 0, 0, 0, 0)
```

An example of a compressed message is 0x932e ac71 66d8 6fb1 592b dc9a 9734 d847 a733 874e 1bcb cd51 b5dc 9659 9d6a, which decompresses to give the output 0x0000 932e 0001 b166 d86f b100 1a2b 0003 9a97 34d8 0007 0001 3387 4e00 08dc 9651 b5dc 9600 599d 6a. Executing the code costs 130 UDVM cycles.

As the code is run, the input_bit_order changes through all possible values to check usage of the F and P bits. The number of bits or bytes to input each time is taken from the value of input_bit_order. For each INPUT-BYTES instruction, the remaining bits of the byte are thrown away. The P-bit always changes on the byte boundary so no bits are thrown away. The sequence is the following:

<pre>Input_bit_order (bin</pre>) Input bits	Input bytes	Output
000	0		0x0000
010		2	0x932e
011	3		0x0001
101		5	0xb166 d866 b1
110	6		0x001a
001		1	0x2b
010	2		0x0003
100		4	0x9a97 34d8
101	5		0x0007
000		0	
001	1		0x0001
011		3	0x3384 4e
100	4		0x0008
110		6	0xdc96 51b5 dc96
111	7		0×0059
010		2	0x9d6a
011	3 - no bits	left so term	inate

2.13. Stack Manipulation

This section gives assembly code to test the PUSH, POP, CALL, and RETURN instructions. The code is designed to test that the following boundary cases have been correctly implemented:

- 1. The stack manipulation instructions overwrite the UDVM register stack location.
- 2. The CALL instruction specifies a reference operand rather than an absolute value.
- 3. The PUSH instruction pushes the value contained in stack_fill onto the stack.
- 4. The stack_location register contains an odd integer.

2.15. State Creation

This section gives assembly code to test the STATE-CREATE and STATE-FREE instructions. The code is designed to test that the following boundary cases have been correctly implemented:

0808 0909, and a total of 131 UDVM cycles are used.

- 1. An item of state is created that duplicates an existing state item.
- 2. An item of state is freed when the state has not been created.
- 3. An item of state is created and then freed by the same message.
- 4. The STATE-FREE instruction frees a state item by sending fewer bytes of the state_identifier than the minimum_access_length.

- 5. The STATE-FREE instruction has partial_identifier_length operand shorter than 6 or longer than 20.
- 6. The STATE-FREE instruction specifies a partial_identifier that matches with two state items in the compartment.
- 7. The bytes of the identifier are written to the position specified in the STATE-FREE instruction after the STATE-FREE instruction has been run (and before END-MESSAGE).

Upon reaching the END-MESSAGE instruction, the UDVM does not output any decompressed data, but instead may make one or more state creation or state free requests to the state handler. Assuming that the application does not veto the state creation request (and that sufficient state memory is available) the code results in 0, 1, or 2 state items being present in the compartment.

The following table lists ten different compressed messages, the states created and freed by each, the number of states left after each message, and the number of UDVM cycles used. There are 3 state creation instructions:

create state_a, which has hash identifier1
create state_b (in END-MESSAGE), which is identical to state_a

create state_a2, which has a different identifier, but the first 6 bytes are the same as those of identifier1.

2.16. STATE-ACCESS

This section gives assembly code to test the STATE-ACCESS instruction. The code is designed to test that the following boundary cases have been correctly implemented:

- 1. A subset of the bytes contained in a state item is copied to the UDVM memory.
- 2. Bytes are copied from beyond the end of the state value.
- 3. The state_instruction operand is set to 0.
- 4. The state cannot be accessed because the partial state identifier is too short.
- 5. The state identifier is overwritten by the state item being accessed.

The following bytecode needs to be run first to set up the state for the rest of the test.

```
at (128)
END-MESSAGE (0, 0, state_length, state_start, 0, 20, 0)
; The bytes between state_start and state_end are derived from

compressed message is 0x01, then the output of the code is also
0 \times 7465 7374 but in this case using a total of 15 UDVM cycles. If the
compressed message is 0x02, 0x03, or 0x04, then decompression failure
occurs.
```

3. Torture Tests for Dispatcher

The following sections give code to test the various functions of the SigComp dispatcher.

3.1. Useful Values

This section gives assembly code to test that the SigComp "Useful Values" are correctly initialized in the UDVM memory. It also tests that the UDVM is correctly terminated if the bytecode uses too many UDVM cycles or tries to write beyond the end of the available memory.

The code tests that the following boundary cases have been correctly implemented:

- 1. The bytecode uses exactly as many UDVM cycles as are available (in which case no problems should arise) or one cycle too many (in which case decompression failure should occur). A liberal implementation could allow more cycles to be used than are strictly available, in which case decompression failure will not occur. This is an implementation choice. If this choice is made, the implementer must be sure that the cycles are checked eventually and that decompression failure does occur when bytecode uses an excessive number of cycles. This is tested in Section 3.2.
- 2. The bytecode writes to the highest memory address available (in which case no problems should arise) or to the memory address immediately following the highest available address (in which case decompression failure must occur).

                            ; Succeed when input byte is 0x00
                            ; Fail when input byte is 0x01
INPUT-BYTES (1, check_memory_lsb, decompression_failure)
ADD ($check_memory, $udvm_memory_size)
SUBTRACT ($check_memory, 1)
COPY (32, 1, $check_memory)
:test_udvm_cycles
INPUT-BYTES (1, check_cycles_lsb, decompression_failure)
; Work out the total number of cycles available to the UDVM
; total_UDVM_cycles = cycles_per_bit * (8 * message_size + 1000)
       = cycles_per_bit * (8 * (partial_state_id_length + 3) + 1000)
LOAD (remaining_cycles, $partial_state_id_length)
ADD ($remaining_cycles, 3)
MULTIPLY ($remaining_cycles, 8)
ADD ($remaining_cycles, 1000)
MULTIPLY ($remaining_cycles, $cycles_per_bit)
ADD ($remaining_cycles, $check_cycles)
set (cycles_used_by_bytecode, 856)
```

The bytecode must be executed a total of four times in order to fully test the SigComp Useful Values. In the first case, the bytecode is uploaded as part of the SigComp message with a 1-byte compressed message corresponding to the version of SigComp being run. This causes the UDVM to request creation of a new state item and uses a total of 968 UDVM cycles.

Subsequent tests access this state by uploading the state identifier as part of the SigComp message. Note that the SigComp message should not contain a returned feedback item (as this would cause the bytecode to calculate the total number of available UDVM cycles incorrectly).

A 3-byte compressed message is required for the second and subsequent cases, the first byte of which is the version of SigComp in use, 0xnn. If the message is 0xnn0000, then the UDVM should successfully terminate using exactly the number of available UDVM cycles. However, if the message is 0xnn0001, then the UDVM should use too many cycles and hence terminate with decompression failure. Furthermore, if the message is 0xnn0100, then decompression failure must occur because the UDVM attempts to write beyond its available memory.

3.2. Cycles Checking

As discussed in Section 3.1, it is possible to write an implementation that takes a liberal approach to checking the cycles used and allows some extra cycles. The implementer must be sure that decompression failure does not occur too early and that in the case of excessive use of cycles, decompression failure does eventually occur. This test checks that:

1. Decompression failure occurs eventually when there is an infinite loop.

```
at (64)
:byte_copy_left
                         pad (2)
:byte_copy_left
:byte_copy_right
                         pad (2)
:value
                         pad (2)
:copy_next
                          pad (2)
at(128)
MULTILOAD (byte_copy_left, 4, 32, 41, 0, 34)
                                ; Set up a 10-byte buffer
                                 ; Set the value to copy
                                 ; Copy it 100 times,
                                 ; output the value,
                                 ; increment the counter
:loop
COPY (value, 2, $byte_copy_left)
COPY-OFFSET (2, 100, $copy_next)
OUTPUT (value, 2)
ADD ($value, 1)
JUMP (loop)
```

If the cycles are counted exactly and cycles per bit (cpb) = 16, then decompression failure will occur at COPY-OFFSET when value = 180 = 0xB4. If cpb = 32, then decompression failure will occur when value = 361 = 0x0169. If they are not counted exactly, then decompression failure MUST occur eventually.

3.3. Message-based Transport

This section provides a set of messages to test the SigComp header over a message-based transport such as UDP. The messages test that the following boundary cases have been correctly implemented:

- 1. The UDVM bytecode is copied to different areas of the UDVM memory.
- 2. The decompression memory size is set to an incorrect value.
- 3. The SigComp message is too short.
- 4. The destination address is invalid.

The basic version of the code used in the test is given below. Note that the code is designed to calculate the decompression memory size based on the Useful Values provided to the UDVM:

```
:udvm_memory_size
                             pad (2)
:cycles_per_bit
                             pad (2)
:sigcomp_version
                             pad (2)
:state_length
                             pad (2)
at (128)
:code_start
; udvm_memory_size for message-based transport
; = DMS - total_message_size
ADD ($udvm_memory_size, total_message_size)
OUTPUT (udvm_memory_size, 2)
END-MESSAGE (0, 0, 0, 0, 0, 1)
:code_end
set (header_size, 3)
set (code_size, (code_end - code_start))
set (total_message_size, (header_size + code_size))
A number of complete SigComp messages are given below, each
containing some or all of the above code. In each case, it is
indicated whether the message will successfully output the
decompression memory size or whether it will cause a decompression
failure to occur (together with the reason for the failure):
SigComp message:
                              Effect:
0xf8
                              Fails (message too short)
0xf800
                              Fails (message too short)
0xf800 e106 0011 2200 0223
                            Outputs the decompression_memory_size
0x0000 0000 0000 01
0xf800 f106 0011 2200 0223 Fails (message too short)
0x0000 0000 0000 01
0xf800 e006 0011 2200 0223 Fails (invalid destination address)
0x0000 0000 0000 01
0xf800 ee06 0011 2200 0223 Outputs the decompression_memory_size
0x0000 0000 0000 01
```

The messages should be decompressed in the order given to check that an error in one message does not interfere with the successful decompression of subsequent messages.

The two messages that successfully decompress each use a total of 5 UDVM cycles.

3.4. Stream-based Transport

This section provides a byte stream to test the SigComp header and delimiters over a stream-based transport such as TCP. The byte stream tests all of the boundary cases covered in Section 3.2, as well as the following cases specific to stream-based transports:

- 1. Quoted bytes are used by the record marking scheme.
- 2. Multiple delimiters are used between the same pair of messages.
- 3. Unnecessary delimiters are included at the start of the stream.

The basic version of the code used in the test is given below. Note that the code is designed to calculate the decompression memory size based on the Useful Values provided to the UDVM:

```
:udvm_memory_size
                               pad (2)
:cycles_per_bit
:sigcomp_version
                              pad (2)
                              pad (2)
:partial_state_id_length pad (2)
:state_length
                              pad (2)
at (128)
; udvm_memory_size for stream based transport = DMS / 2
MULTIPLY ($udvm_memory_size, 2)
OUTPUT (udvm_memory_size, 2)
OUTPUT (test_record_marking, 5)
END-MESSAGE (0, 0, 0, 0, 0, 0, 0)
:test_record_marking
byte (255, 255, 255, 255, 255)
```

RFC 4465

The above assembly code has been compiled and used to generate the following byte stream:

Note that this byte stream can be divided into five distinct portions (two SigComp messages and three sets of delimiters) as illustrated below:

Portion of byte stream: Meaning:

Oxffff Delimiter

0xf801 7108 0002 2200 0222 a092 0523 First message 0x0000 0000 000f 00ff 03ff ffff

Oxffff ffff Delimiter

0xf801 7e08 0002 2200 0222 a3d2 0523 Second message 0x0000 0000 000f 04ff ffff ff

Oxffff ffff Delimiter

When the complete byte stream is supplied to the decompressor dispatcher, the record marking scheme must use the delimiters to partition the stream into two distinct SigComp messages. Both of these messages successfully output the decompression memory size (as a 2-byte value), followed by 5 consecutive 0xff bytes to test that the record marking scheme is working correctly. A total of 11 UDVM cycles are used in each case.

It must also be checked that the dispatcher can handle the same error cases as covered in Section 3.2. Each of the following byte streams should cause a decompression failure to occur for the reason stated:

Byte stream: Reason for failure:

0xf8ff ff Message too short

0xf800 ffff Message too short

0xf801 8108 0002 2200 0222 a092 0523 ffff Message too short

0x0000 0000 0000 00ff 00ff 03ff ffff

0x0000 0000 0000 00ff 04ff ffff ff

Surtees & West Informational [Page 35]

3.5. Input Past the End of a Message

This section gives assembly code to test that the implementation correctly handles input past the end of a SigComp message. The code is designed to test that the following boundary cases have been correctly implemented:

- 1. An INPUT instruction requests data that lies beyond the end of the message. In this case, the dispatcher should not return any data to the UDVM. Moreover, the message bytes held by the dispatcher should still be available for retrieval by subsequent INPUT instructions.
- 2. The INPUT-BYTES instruction is used after part of a byte has been input (e.g., by the INPUT-BITS instruction). In this case, the remaining partial byte must be discarded, even if the INPUT-BYTES instruction requests data that lies beyond the end of the message.

:end_message
END-MESSAGE (0, 0, 0, 0, 0, 0)
```

If the compressed message is 0xfffa 0068 6921, then the code terminates successfully with the output 0x6869 21, and a total of 23 UDVM cycles are used. However, if the compressed message is 0xfffa 0068 69, then decompression failure occurs (at the final INPUT-BITS).

4. Torture Tests for State Handler

The following sections give code to test the various functions of the SigComp state handler.

4.1. SigComp Feedback Mechanism

This section gives assembly code to test the SigComp feedback mechanism. The code is designed to test that the following boundary cases have been correctly implemented:

- 1. Both the short and the long versions of the SigComp feedback item are used.
- The chain of returned SigComp parameters is terminated by a nonzero value.

END-MESSAGE (requested_feedback_location,
returned_parameters_location, 0, 0, 0, 0, 0)
:decompression_failure
DECOMPRESSION-FAILURE
```

When the above code is executed, it supplies a requested feedback item to the state handler. If the compressed message is 0x00, then the short (1-byte) version of the feedback is used. Executing the bytecode in this case costs a total of 52 UDVM cycles. Assuming that the feedback request is successful, the feedback item should be returned in the first SigComp message to be sent in the reverse direction. The SigComp message returning the feedback should begin as follows:

+++								
1	1	1	1	1	1	X		first header byte
++			+	+	++-	+-	+	
								returned feedback field
++			+	+	++-	+-	+	

So the first 2 bytes of the returning SigComp message should be 0xfn7f where n=c, d, e, or f (the choice of n is determined by the compressor generating the returning SigComp message, which is not under the control of the above code).

If the compressed message is 0x01, then the long version of the feedback item is used. Executing the bytecode in this case costs a total of 179 UDVM cycles and the SigComp message returning the feedback should begin as follows:

So the first 129 bytes of the SigComp message should be $0xfnff\ 0102\ 0304\ \dots\ 7e7f$ where n = c, d, e, or f as above.

As well as testing the requested and returned feedback items, the above code also announces values for each of the SigComp parameters. The supplied version of the code announces only the minimum possible values for the cycles_per_bit, decompression_memory_size, state_memory_size, and SigComp_version (although this can easily be adjusted to test different values for these parameters).

The code should also announce the availability of state items with the following partial state identifiers:

```
0x0001 0203 0405
0x0001 0203 0405 0607 0809 0a0b
0x0001 0203 0405 0607 0809 0a0b 0c0d 0e0f 1011 1213
```

Note that different implementations may make use of the announcement information in different ways. It is a valid implementation choice to simply ignore all of the announcement data and use only the minimum resources that are guaranteed to be available to all endpoints. However, the above code is useful for checking that an endpoint interprets the announcement data correctly (in particular ensuring that it does not mistakenly use resources that have not in fact been announced).

4.2. State Memory Management

The following section gives assembly code to test the memory management features of the state handler. The code checks that the correct states are retained by the state handler when insufficient memory is available to store all of the requested states.

The code is designed to test that the following boundary cases have been correctly implemented:

- 1. A state item is created that exceeds the total state_memory_size for the compartment.
- 2. States are created with a non-zero state_retention_priority.
- 3. A new state item is created that has a lower state_retention_priority than existing state items in the compartment.

For the duration of this test, it is assumed that all states will be saved in a single compartment with a state_memory_size of 2048 bytes.

```

The above code must be executed a total of 7 times in order to complete the test. Each time the code is executed, a 1-byte compressed message should be provided as below. The effects of the messages are given below. States are described in the form (name, x, y) where name corresponds to the name of the identifier in the mnemonic code, x is the length of the state, and y is the retention priority of the state.

Message:	Effect:	#cycles:
0x00	<pre>create states: (a,0,0),</pre>	811
	(b,256,1),	
	(c,512,2)	
0×01	create states:	2603
	(d,768,3),	
	(e,1024,4) - deleting a, b, c	
0x02	create states:	811
	(c,512,2), - deleting d	
	(b,256,1),	
	(a,0,0)	
0x03	access states a,b,c,e	1805
0×04	access state d - not present so decompression fa	ilure
0×05	create states:	2057
	(large, 2048,0) - deleting a, b, c, e	
0x06	access large state	1993

Note that as new states are created, some of the existing states will be pushed out of the compartment due to lack of memory.

4.3. Multiple Compartments

This section gives assembly code to test the interaction between multiple SigComp compartments. The code is designed to test that the following boundary cases have been correctly implemented:

at (64)

- 1. The same state item is saved in more than one compartment.
- 2. A state item stored in multiple compartments has the same state identifier but a different state_retention_priority in each case.
- 3. A state item is deleted from one compartment but still belongs to a different compartment.
- 4. A state item belonging to multiple compartments is deleted from every compartment to which it belongs.

The test requires a total of three compartments to be available, which will be referred to as Compartment 0, Compartment 1, and Compartment 2. Each of the three compartments should have a state_memory_size of 2048 bytes.

The assembly code for the test is given below:

```
:byte_copy_left
                              pad (2)

byte (194, 117, 148, 29, 215, 161)
byte (72, 135, 156, 141, 233, 14)
```

The above code must be executed a total of 9 times in order to complete the test. Each time the code is executed, a 1-byte compressed message N should be provided, taking the values 0x00 to 0x08 in ascending order (so the compressed message should be 0x00 the first time the code is run, 0x01 the second, and so on).

If the code makes a state creation request, then the state must be saved in Compartment (N modulo 3).

When the compressed message is 0x00, 0x01, or 0x02, the code makes four state creation requests in compartments 0, 1, and 2, respectively. This creates a total of seven distinct state items referred to as State a through State g. The states should be distributed among the three compartments as illustrated in Figure 1 (note that some states belong to more than one compartment).

When the compressed message is 0x03 or 0x04, the code overwrites all of the states in Compartments 0 and 1, respectively. This means that States a, b, and e will be unavailable because they are no longer present in any of the three compartments.

When the compressed message is 0x05, the code checks that the States c, d, f, and g are still available. Decompression should terminate successfully in this case.

When the compressed message is 0x06, 0x07, or 0x08, the code attempts to access States a, b, and e, respectively. Decompression failure should occur in this case because the relevant states are no longer available.

The cost in UDVM cycles for each compressed message is given below (except for messages 0x06, 0x07, and 0x08 where decompression failure should to occur):

Compressed message: 0x00 0x01 0x02 0x03 0x04 0x05 0x06 0x07 0x08

Cost in UDVM cycles: 1809 1809 1809 1993 1994 1804 N/A N/A N/A

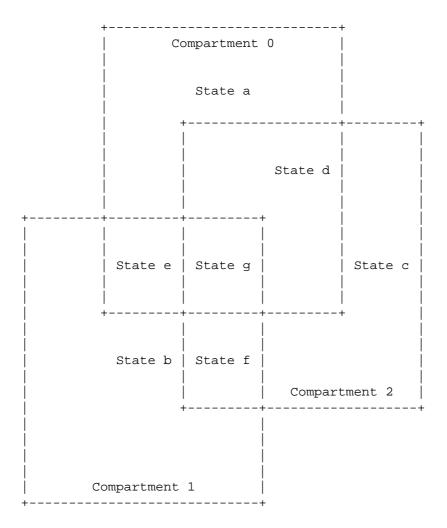

Figure 1: States created in the three compartments

4.4. Accessing RFC 3485 State

This section gives assembly code to test accessing SIP-SDP static dictionary state [3]. The code first accesses the state and then outputs the result.

at (32)
:input pad (1)
:input2 pad (1)
:input3 pad (1)

Surtees & West Informational [Page 49]

```
at (128)

STATE-ACCESS (sip_dictionary, 20, 0xcfe, 1, input, 0)

STATE-ACCESS (sip_dictionary, 6, 0xcff, 1, input2, 0)

STATE-ACCESS (sip_dictionary, 12, 0xd00, 1, input3, 0)

OUTPUT (input, 3)

END-MESSAGE (0, 0, 0, 0, 0, 0, 0)

:sip_dictionary

byte (0xfb, 0xe5, 0x07, 0xdf, 0xe5, 0xe6)

byte (0xaa, 0x5a, 0xf2, 0xab, 0xb9, 0x14)

byte (0xce, 0xaa, 0x05, 0xf9, 0x9c, 0xe6)

byte (0x1b, 0xa5)
```

The output of the code is 0x5349 50, and the cost is 11 UDVM cycles.

4.5. Bytecode State Creation

This section gives assembly code to test storing bytecode using END-MESSAGE and later loading the bytecode using a partial state identifier within the SigComp header. The assembly code is designed to test the following cases:

- 1. The bytes to be saved are changed after the state create request has been made.
- 2. The uploaded bytecode is modified before execution.
- 3. The bytecode is loaded using the partial state identifier and is modified before execution.
- 4. The bytecode is loaded to an address lower than 128, using the partial state identifier.
- 5. The bytecode is loaded using the partial state identifier. Part of the loaded memory is reserved area, which is overwritten after loading the bytecode.
- 6. The loading of the bytecode fails because the partial state identifier is too short.

```
at (30)
:save_area1
set (saved_instr1, (save_areal + (code_start2 - start_saved))) ; = 33
at (80)

2	0x4f4b 31	7
3	0x4f4b 32	5
4	0x0000 32	5
5	None	Decompression failure

First message: mnemonic code annotated above

0xf804 6112 a0be 081e 2008 1e21 060a 0e23 be03 12a0 be08 a050 2008 0xa050 a053 140a 2008 a050 a053 0c0a 1606 004f 4b31 1c01 a0b3 fc22 0xa0a8 0323 0000 0da0 a8a0 ab06 0a4f 4b32 22a0 5003 2302

Second message: access and run last state saved by previous message - 'ok1', INPUT-BYTES, OUTPUT, END-MESSAGE.

0xf905 b88c e72c 9103

Third message: access and run state from save_area2 with 12 bytes of state identifier - 'ok2', INPUT-BYTES, OUTPUT, END-MESSAGE.

0xfb24 63cd ff5c f8c7 6df6 a289 ff

Fourth message: access and run state from save_areal. The state is 'ok2', INPUT-BYTES, OUTPUT, END-MESSAGE but the first two bytes should be overwritten when initialising UDVM memory.

0xf95b 4b43 d567 83

Fifth message: attempt to access state from save_area2 with fewer than 20 bytes of state identifier.

0xf9de 8126 1199 1f

5. Security Considerations

This document describes torture tests for the SigComp protocol RFC 3320 [2]. Consequently, the security considerations for this document match those of SigComp.

In addition, the torture tests include tests for a significant number of "boundary and error cases" for execution of the UDVM bytecode. Boundary and error problems are common vectors for security attacks, so ensuring that a UDVM implementation executes this set of torture tests correctly should contribute to the security of the implementation.

6. Acknowledgements

Thanks to Richard Price and Pekka Pessi for test contributions and to Pekka Pessi and Cristian Constantin, who served as committed working group document reviewers.

Appendix A. UDVM Bytecode for the Torture Tests

The following sections list the raw UDVM bytecode generated for each test. The bytecode is presented in the form of a complete SigComp message, including the appropriate header. It is followed by input messages, the output they produce, and where the decompression succeeds the number of cycles used.

In some cases, the test is designed to be run several times with different compressed messages appended to the code. In the cases where multiple whole messages are used for a test, e.g., Appendix A.2.3, these are supplied. In the case where decompression failure occurs, the high-level reason for it is given as a reason code defined in NACK [4].

Note that the different assemblers can output different bytecode for the same piece of assembly code, so a valid assembler can produce results different from those presented below. However, the following bytecode should always generate the same results on any UDVM.
